Abstract: We propose a change-point approach for testing the constancy of regression parameters in a linear profile data set (panel data in econometrics). Each sample collected over time in the historical data set consists of several multivariate observations for which a linear regression model is appropriate. The question now is whether all of the profiles follow a linear regression model with the same parameter vector or whether a change occurred in one or more model parameters after a special sample. We use the partial sum operator in several dimensions to test the null hypothesis "H₀: no change-point occurred" and propose a non-parametric size α-test. In Bischoff and Gegg (2010) we compared our proposed method with the likelihood-ratio-test by Mahmoud et al. (2007) in a simulation study. By these simulations we could show that our procedure can, in contrast to the likelihood-ratio-test, even be applied to the non-normal case. In this paper, however, we show how to compute our proposed test statistic step-by-step by considering an artificial data set.

Key words: change-point problem; panel data; statistical process control; linear regression
1. Introduction

We investigate a linear profile data set for change-points. In economics, linear profile data are also known as "panel data". Note that linear profile data are assumed to be ordered in a natural way. In most of the applications the profiles will be sampled sequentially and so time is the ordering variable. We attack this problem by using the results given in Bischoff and Gegg (2010), where a linear regression model with p-variate response was considered. In order to find change-points in regression models we investigated there the partial sums of the least squares residuals. Without specifying the error a nonparametric test (as for instance a test of Kolmogorov-Smirnov type) can then be applied to the limit process of the partial sums in order to test whether a change-point does or does not occur. MacNeill (1978a,b) and Bischoff (1998, 2002) give basic theoretical results concerning the residual partial sums process for univariate response, whereas Bischoff (2010) demonstrates this approach in case of univariate regression by using an example from quality control. Note that the residual partial sums technique can also be used to check asymptotically for regression with multivariate correlated response (Bischoff and Gegg, 2010).

Our proposed method is a two-step-procedure: In a first step, we estimate the parameter vectors for every profile. In a second step we analyze these estimations which build a linear model with multiple correlated response under the null hypothesis that the profile data have no change-point.

Mahmoud et al. (2007) also attacked the described change-point problem and proposed a modification of a likelihood ratio test (LRT) for the case of simple linear regression with normally distributed error terms. By asymptotic considerations our method does not need assumptions about the distribution of the error terms and so it is more robust against departure from normal distribution, see Bischoff and Gegg (2010). A further advantage of our procedure is that the alternative hypothesis does not have to be specified.

2. Linear Profile Data

In practice, one often wants to test whether all of a fixed number \( m \), say, of independent samples follow the same known linear model. To be more precise let

\[
W(j) = X \beta(j) + \varepsilon(j), \quad \beta(j) \in \mathbb{R}^p \text{ unknown},
\]

be a linear model for every profile \( j \in \{1, \ldots, m\} \), where

\((A1)\) \( X \in \mathbb{R}^{n \times p} \) is the corresponding design matrix of explanatory variables with \( \text{rank}(X) = p \leq n \),

\((A2)\) and \( \varepsilon(j) \) is the vector with iid components \( \varepsilon_1^{(j)}, \ldots, \varepsilon_n^{(j)} \) having mean 0 and variance \( \sigma^2 \).

Note that assumption \((A1)\) in particular claims that the same design is used for each profile \( j \). Furthermore, since different profiles are assumed to be independent, so are \( \varepsilon^{(n)}, \ldots, \varepsilon^{(m)} \). In the sequel we assume model (1), together with the assumptions \((A1) - (A2)\), to be true for each \( j \). Model (1) is called the "\( j \)-th Linear Profile" and the aim is to test for a change-point in the parameter vector. Since the profiles have a natural ordering we can formulate the corresponding hypothesis by
\[ H_0 : \beta = \beta^{(1)} = \ldots = \beta^{(m)} \quad \text{vs.} \quad H_1 : \exists m_0 \in \{1, \ldots, m-1\} : \beta^{(1)} = \beta^{(2)} = \ldots = \beta^{(m_0)} \neq \beta^{(m_0+1)} \quad (2) \]

and so the testing problem is indeed a change-point problem. In order to check (2) we estimate \( \hat{\beta}^{(0)} \) by the least-squares estimator \( \hat{\beta}^{(j)} \). With our assumptions (A1)-(A2) we have

\[
E(\hat{\beta}^{(j)}) = \beta^{(j)} \quad \text{and} \quad \text{Cov}(\hat{\beta}^{(j)}) = \sigma^2 (X'X)^{-1} =: \Sigma. \quad (3)
\]

In case \( \sigma^2 \) is unknown, our proposed procedure can also be used by replacing \( \sigma^2 \) with a consistent estimator for \( \sigma^2 \) under \( H_0 \). So we can assume without loss of generality, \( \Sigma \) is a known positive definite matrix. Furthermore \( \hat{\beta}^{(1)}, \ldots, \hat{\beta}^{(m)} \) are independent since the different samples \( W^{(1)}, \ldots, W^{(m)} \) are assumed to be independent. Let

\[
Y := \begin{pmatrix} \hat{\beta}^{(1)T} \\ \vdots \\ \hat{\beta}^{(m)T} \end{pmatrix} \quad \text{be the} \ m \times p \text{matrix containing the least-squares estimations and let}
\]

\[
Z := \begin{pmatrix} \hat{\beta}^{(1)T} - \beta^T \\ \vdots \\ \hat{\beta}^{(m)T} - \beta^T \end{pmatrix}. \quad \text{If (1) and (2)}
\]

hold true, then (3) leads to the following model:

\[ Y = 1_m \beta^T + Z \quad \text{with} \quad EZ = 0, \ \text{Cov(vec}(Z^T)) = I_m \otimes \Sigma \quad \text{and} \ \beta \in \mathbb{R}^p \text{ unknown parameter vector.} \quad (4) \]

Thereby \( 1_m \in \mathbb{R}^m \) is the vector whose components are all equal to 1, \( I_m \) is the \( m \times m \) identity matrix, "\( \otimes \)" denotes the Kronecker-Product and "vec" is the well-known vec-operator (Harville, 1997).

Conversely, if (2) is false and (1) together with (A1)-(A2) still holds true, then a change-point occurred, and (4) does not hold. Therefore we can test hypothesis (2) by checking the linear model (4). Bischoff and Gegg (2010) formulated a procedure which can be used to check a more general model by using multiple partial sum processes. Below we apply this method to our problem.

### 3. Residual Partial Sums Process

In order to test the hypotheses (2), we investigate the partial sums of the \( p \)-dimensional residuals in model (4). For that we use the partial sum operator \( T_m \), which embeds a vector \( a = (a_1, \ldots, a_m)^T \in \mathbb{R}^m \) in the space \( C([0,1]) \) by

\[
T_m \begin{pmatrix} a_1 \\ \vdots \\ a_m \end{pmatrix} (z) = \sum_{i=1}^{\lfloor mz \rfloor} a_i + (mz - \lfloor mz \rfloor) a_{\lfloor mz \rfloor + 1}, \quad z \in [0,1],
\]

where \( \lfloor z \rfloor := \max \{l \in \mathbb{Z} \mid l \leq z\} \) and \( \sum_{i=1}^{\lfloor 0 \rfloor} a_i = 0 \). Figure 1 shows the resulting graph of the partial sum operator \( T_m \) applied to a vector \( a \in \mathbb{R}^m \). The partial sum operator \( T_{m,vp} \) embeds
International Symposium on Stochastic Models in Reliability Engineering, Life Sciences and Operations Management (SMRLO’10)

\[ R^{mp} = R^n \times \ldots \times R^n \] in the space \( C(0,1, R^p) = C(0,1) \times \ldots \times C(0,1) \).

We define \( T_{mp} \) with the help of \( T_m \). For this, let \( A \in R^{mp} \) be an \( m \times p \) matrix with columns \( a^{(1)}, \ldots, a^{(p)} \), then:

\[
T_{mp} : \begin{cases}
R^{mp} \rightarrow C(0,1) \times \ldots \times C(0,1) \\
A \mapsto T_{mp}(A)(z) = (T_m(a^{(1)})(z), \ldots, T_m(a^{(p)})(z)) , \quad z \in [0,1] 
\end{cases}
\]

The partial sum operator has gained a lot of interest especially because of the well-known Donsker-Theorem for an iid sequence of centered random variables. Iglehart (1968) formulated a vector-valued version of this theorem:

**Theorem 1**

Let \((\xi_i)_{i=1}^\infty\) be an iid sequence of random variables with values in \( R^p \) and

\[ E \xi_1 = 0, \quad \text{Cov}(\text{vec}(Z^i)) = I_m \otimes \Sigma \]

with \( \Sigma \) positive definite. Then:

\[
\frac{1}{\sqrt{m}} \sum_{i=1}^{m-1/2} T_{mp}(\xi_1^{T}, \ldots, \xi_m^{T}) \xrightarrow{D} B^p \quad \text{with} \quad m \to \infty,
\]

where \( B^p \) is the \( p \)-dimensional Brownian motion with independent components and \( \xrightarrow{D} \) means weak convergence.

The residuals of the linear model (4) are correlated and through this they do not fulfill the iid assumption of the preceding theorem. However, Bischoff and Gegg (2010) used the vector-valued version of the Donsker-Theorem to establish the \( p \)-dimensional residual
partial sums process in case of a multivariate linear model with multiple response. It is a projection of the Brownian motion $B^0$ on a certain subspace. As a special case, we state the following result:

**Theorem 2**

Consider model (4), i.e. $Y = 1_m \beta^T + Z$ with $EZ = 0$, $\text{Cov}(\text{vec}(Z)) = I_m \otimes \Sigma$ and $\beta \in \mathbb{R}^p$ unknown parameter vector.

Then, under $H_0: \beta = \cdots = \beta^{(m)}$, we have for the residuals $Y - \hat{Y}$ and $m \to \infty$,

$$
\frac{1}{\sqrt{m}} \Sigma^{-1/2} T_{\text{vec}}(Y - \hat{Y})^T \xrightarrow{D} B^0_p,
$$

(5)

where $B^0_p$ is the $p$-dimensional Brownian bridge.

**4. Test for Linear Profile Data**

Under the null hypothesis the residual partial sums limit process (cf. Theorem 2) is given by $B^0_p$, the so-called standard $p$-dimensional Brownian bridge on $[0,1]$. An intuitive one-dimensional test statistic is the maximum of the Euclidean norm of the $p$-dimensional process. To be more precise let

$$ R_m(t) := \frac{1}{\sqrt{m}} \Sigma^{-1/2} T_{\text{vec}}(Y - \hat{Y})(t), \quad t \in [0,1]. $$

Then our proposed test statistic is $\max_{t \in [0,1]} \| R_m(t) \|$, where $\| \cdot \|$ is the Euclidean norm in $\mathbb{R}^p$, i.e. $\| (x_1, \dots, x_p) \|^2 = \sum_{i=1}^p x_i^2$. Because of the "Continuous Mapping Theorem" (Billingsley 1999), we have the following convergence under $H_0$:

$$
\| R_m \| \xrightarrow{D} \| B^p \| \quad \text{for } m \to \infty.
$$

(6)

Note that the limit process is the well-known Bessel bridge. In order to check (4) we apply a test of Kolmogorov-Smirnov type to the Bessel bridge and we get an asymptotic size $\alpha$-test, $\alpha \in (0,1)$, by

Reject $H_0 \iff \sup_{t \in [0,1]} \| R_m(t) \| > k_\alpha$.

Thereby $k_\alpha > 0$ is a constant such that $P(\sup_{t \in [0,1]} \| B^p_0(t) \| > k_\alpha) = \alpha$. Note that for given $\alpha$, the corresponding value $k_\alpha$ can be explicitly calculated. Kiefer (1959) gives a closed form for the cumulative distribution function of the Bessel bridge. We cite from his article concrete values for $k_\alpha$ in case $p = 2,\ldots,5$ and $\alpha = 0.1, 0.05, 0.01$ in Table 1:

5. Numerical Example

5.1. Profile Data and Parameter Estimation

As a concrete example of application, we study the situation, that a change takes place after profile 4 of $m = 6$ profiles – both in the intercept and in the quadratic term in a quadratic model. For each profile, we simulated $n = 10$ observations according to

$$W_i^{(j)} = \alpha_1^{(j)} + x_i + \alpha_2^{(j)} x_i^2 + 2 \cdot \varepsilon_{ij}, i = 1, \ldots, 10, j = 1, \ldots, 6.$$ 

Thereby

- $\alpha_1^{(j)} = 0$ for $j = 1, \ldots, 4$ and $\alpha_1^{(j)} = 1$ for $j = 5, 6$ (shift in intercept)
- $\alpha_2^{(j)} = 0.1$ for $j = 1, \ldots, 4$ and $\alpha_2^{(j)} = 0.12$ for $j = 5, 6$ (shift in quadratic term)
- $x_1 = 0, x_2 = \frac{10}{9}, x_3 = \frac{20}{9}, \ldots, x_{10} = 10$,
- $\varepsilon_{ij}$ is a sequence of standardized iid random variables having lognormal distribution.

Figure 2. Simulated profiles $W_i^{(1)}, \ldots, W_i^{(6)}$ (color in plot: black) and $W_i^{(5)}, W_i^{(6)}$ (grey).

Figure 2 shows the simulated profile data under study. Let
\[ X : = \begin{pmatrix} 1 & x_{11} & x_{12} \\ \vdots \\ 1 & x_{110} & x_{110}^2 \end{pmatrix} \in \mathbb{R}^{m \times p} \]

be the design matrix for each profile. Consequently, we have \( p = \text{rank}(X) = 3 \). We fit for each profile the model

\[ W^{(j)} = X \begin{pmatrix} \beta_0^{(j)} \\ \vdots \\ \beta_2^{(j)} \end{pmatrix} + \epsilon^{(j)}, \quad (7) \]

where \( \epsilon^{(j)} \) is a random vector with \( \mathbb{E} \epsilon^{(j)} = 0 \) and \( \text{Cov} \epsilon^{(j)} = \sigma^2 I_p \). We estimate the coefficients by least squares method and get the values \( \hat{\beta}_0^{(j)}, \ldots, \hat{\beta}_2^{(j)} \) shown in Figure 3. With these estimations, we can fit model (4) with \( y = \sigma^2 (XX^T)^{-1} \).

Furthermore, by model (7), we get for each profile \( j \) an estimation for the variance, namely the usual variance estimation

\[ \hat{\sigma}_j^2 = \frac{1}{10-3} (W^{(j)T} (I - X (X^T X)^{-1} X^T) W^{(j)}), \ j = 1, \ldots, 6. \]

Consequently, with our assumptions (A1)-(A2), we can estimate \( \sigma^2 \) by

\[ \hat{\sigma}^2 = \frac{1}{m} \sum_{j=1}^{m} \hat{\sigma}_j^2 = \frac{1}{6} \sum_{j=1}^{6} \hat{\sigma}_j^2. \]

In case of the simulated data mentioned above, we have \( \hat{\sigma}^2 = 3.004228 \).

**Figure 3.** Estimations for parameter vector \( \beta_0^{(1)}, \ldots, \beta_0^{(6)} \) (black) and \( \beta_1^{(1)}, \beta_1^{(6)} \) (grey)
5.2. Test for a Change-Point

Now we are in the position, to calculate our proposed test statistic. Therefore, with

\[ Y := \begin{pmatrix} \hat{\beta}_{(1)}^T \\ \vdots \\ \hat{\beta}_{(6)}^T \end{pmatrix} \text{ and } \hat{Y} \in \mathbb{R}^{6 \times 3} \text{ being the matrix of estimated values in (4), we get:} \]

\[ R_6(t) := \frac{1}{\sqrt{\hat{\sigma}^2}} (X^T X)^{1/2} T_{6 \times 3} (Y - \hat{Y})^T (t), \quad t \in [0, 1]. \]

Then we can determine the value of our test-statistic \( \max_{t \in [0, 1]} ||R_6(t)|| \) and compare with the critical values given in Table 1.

Figure 4 shows the process \( ||R_6(t)|| \) for the data set under study. We get a value for the test statistic of 2.01976 and so we can reject the null hypothesis “\( H_0 \) no change-point” even for \( \alpha = 0.01 \) since the corresponding critical value is \( k_{0.01} = 2.00092 \).

Note that, by using the same random numbers in case “no change-point” (i.e. \( \alpha^{(j)}_1 = 0, \alpha^{(j)}_2 = 0.1 \) for all \( j = 1, \ldots, 6 \)), the test statistic is 0.5036005 and so we consistently cannot reject the null hypothesis to usual sizes.

Consequently, our proposed method leads to good results even in the case of small shifts (see Figure 2) and also in case of non-normal error terms (in the example, we have used log-normally distributed error terms).

![Figure 4. \( ||R_6(t)|| \) with the true position of the change-point (dotted grey line)](image)
